

# THE GENDER GAP IN HOUSING RETURNS\*

PAUL GOLDSMITH-PINKHAM

KELLY SHUE

January 2020

## Abstract

Housing wealth represents the dominant form of savings for American households. Using detailed data on housing transactions across the United States since 1991, we find that single men earn 1.5 percentage points higher unlevered returns per year on housing relative to single women, with couples occupying the intermediate range. The gender gap grows significantly larger after adjusting for mortgage borrowing: men earn 7.9 percentage points higher levered returns per year relative to women. Approximately 45% of the gap in housing returns can be explained by gender differences in the location and timing of transactions. The remaining gap arises primarily from gender differences in execution prices: data on repeat sales reveal that women buy the same property for approximately 2% more and sell for 2% less. Women experience worse execution prices because of differences in the choice of initial list price and negotiated discount relative to the list price. Gender differences in upgrade and maintenance rates, and preferences for housing characteristics and listing agents appear to be less important factors. Overall, the gender gap in housing returns is economically large and can explain 30% of the gender gap in wealth accumulation at retirement.

## I. Introduction

Housing accounts for the majority of most American households' wealth, with Americans investing more in the housing market than in the stock market.<sup>1</sup> Housing also differs from other common forms of household savings, such as bank deposits, bonds, and stocks, in that it is an illiquid and heterogeneous asset with prices determined through bilateral negotiation. Motivated by the existing research showing gender differences in negotiation, financial investment strategies, and preferences for risk and competition (e.g., [Sunden and Surette, 1998](#); [Ayres, 1990](#); [Babcock and Laschever, 2009](#); [Sapienza et al., 2009](#); [Reuben et al., 2015](#); [Niederle and Vesterlund, 2007](#); [Gneezy et al., 2003](#)), we investigate how men and women differ in their financial returns on housing investment.

We use detailed data from CoreLogic covering over 50 million housing transactions and matched property listings across the US from 1991 to 2017. For approximately 9 million transactions for which we can identify homeowner gender, and the initial purchase and eventual sale prices, we compute the homeowner's annualized realized return.

We find that single men earn 1.5 percentage points higher unlevered annualized returns relative to single women. Approximately 45% of this gender gap in raw housing returns can be explained by market timing, i.e., the choice of where and when to buy, and when to sell. Women earn lower returns on housing partly because they tend to buy when aggregate house prices are high and sell when they are low. However, a large gender gap persists even after accounting for market timing. Among men and women who buy and sell in the same zip code and year-month, women still earn 0.8 percentage points lower unlevered annualized returns.

We also find that couples underperform single women on a raw unadjusted basis, but the low returns for couples is primarily due to market timing. After adjusting for the location and timing of purchases and sales, couples significantly outperform single women and underperform single men. Couples also display interesting dynamics, in that they underperform single men at purchase, but outperform single men at sale.

Most U.S. home buyers purchase housing using mortgage debt with loan-to-value ratios of 80 percent or higher, and have not paid down a large fraction of the principal at the time of sale. Therefore, the real return earned is typically a levered return. We find that men outperform women by almost 8 percentage points per year after adjusting for leverage. The growth in the gender gap arises because

---

<sup>1</sup>We plot the share of net worth invested in housing and the stock market for each percentile in the wealth distribution in Appendix Figure [A1](#) using data from the Survey of Consumer Finances.

leverage amplifies raw return differences.

The gender gap in housing returns varies with the business cycle, but exists in all years within our sample and has not declined significantly in recent years. Zip codes with lower average education and income, greater average age, and higher fraction single female are associated with larger gender gaps. However, the gender gap remains large in regions with high average education, income, and house price levels. The gender gap is largest in the right tail of the return distribution, although it also present at the median, and does not significantly reverse in the left tail.

In more detailed analysis, we explore the sources of the gender gap in housing returns. In addition to market timing, we show that the gender gap arises primarily because of a gap in execution prices at the points of purchase and sale. What happens in between purchase and sale, e.g., potential mechanisms in which men invest more in upgrades and maintenance or buying riskier properties that naturally earn higher returns, appear to be less important drivers of the gender gap.

We begin by examining data on repeat sales of the same property. Holding the property fixed, and comparing men and women to transact in the same zip-year-month, women buy the same property for 1-2% more than men and sell for 2-3% less. This difference in transaction prices can be decomposed into gender differences in the choice of list price and negotiated discounts relative to the list price. Again using repeat sales data that allow us to hold the property fixed, we find that female buyers purchase properties that are listed at higher relative prices. Despite buying at higher prices, female sellers also choose to list for lower prices when selling. In addition, women negotiate worse discounts relative to the list price.

The gender gap varies with the match between the gender of the buyer and seller in each transaction. Again exploiting repeat sales, we find that the highest transaction prices are associated with male sellers and female buyers, and the lowest transaction prices are associated with female sellers and male buyers. Female sellers and male buyers are associated with the largest negotiated discounts relative to the list price, while male sellers and female buyers are associated with the smallest discounts.

These findings relating to list prices and negotiated discounts imply that women experience worse execution prices on real estate transactions at the points of purchase and sale. Differences in execution prices should matter much more for the annualized returns of short-term investors than for the returns of long-term buy-and-hold investors. Consistent with this insight, we find that the magnitude of the gender gap in annualized returns decays toward zero with holding length. Homeowners with shorter

tenure in their properties “trade” assets more often, so variation in execution prices matter more for their annualized returns.

We also explore several other potential mechanisms which may drive the gender gap in housing returns. First, men may select properties with characteristics naturally associated with higher returns. In particular, men may purchase riskier properties, such that their higher return represents compensation for the additional risk. Second, men may invest more in housing maintenance and upgrades, such that their real investment return is lower than implied by analysis using only the sale price and purchase price. Third, women may be older, have more children, or have lower education and income, and these demographic factors may contribute to the gender gap in housing returns. Fourth, men may employ better real estate agents when engaging in housing transactions.

We find that differences in preferences for types of homes do not substantially affect the gender gap in housing returns. Men and women indeed differ in their choice of home type (e.g., new construction and number of bedrooms), but controlling for these features does not significantly affect the gender gap in housing returns. Then, using data from the American Housing Survey, we replicate our main results showing a gender gap in housing returns, and find that the gender gap remains large after controlling for age, education, ethnicity, number of children, and income. We also find no gender differences in reported home maintenance investment. In addition to routine maintenance, men may invest more in non-routine upgrades or renovations. Using CoreLogic listings data, we find that men are more likely to list homes that have been upgraded or renovated, but the difference in upgrade rates across genders is small. The gender gap in housing returns remains large in a restricted sample for which the house listing does not mention any upgrades or renovations. Further, we find that the gender gap in returns persists after controlling for listing agent fixed effects, implying that women do not hire systematically worse real estate agents on average.

We can also use the empirical relationship between annualized returns and holding length to assess the importance of the property risk or maintenance explanations. Gender differences in routine maintenance or property risk imply that the the gender gap in annualized housing returns should remain positive as holding length increases. Instead, we observe a gender gap in annualized housing returns that decays toward zero with holding length. This pattern is more consistent with a gap in returns that arises from gender differences in execution prices.

Finally, we examine tight markets where sale volume is high relative to the number of outstanding house listings. As markets tighten, the gender gap in returns, transaction prices, and negotiated

discounts all shrink toward zero. This pattern suggests that bilateral negotiation may be an important driver of the average gender gap in housing returns. As markets tighten, bilateral negotiation is typically replaced with quasi-auctions, in which multiple interested buyers simultaneously bid for homes. The variation in the gender gap by market tightness is also inconsistent with an explanation in which men buy riskier properties or invest more in home maintenance and upgrades, because risk and home improvements should, if anything, be more efficiently priced in liquid markets. Similarly, variation by market tightness is inconsistent with the idea that women earn lower housing returns because they derive greater utility from housing and are therefore willing to pay more for the same house. If so, women should also submit higher bids for homes, leading to lower returns in tight housing markets.

Our analysis is related to existing research examining gender differences in stock market participation, portfolio allocation between stocks and bonds, and investment performance (e.g. [Sunden and Surette, 1998](#); [Bajtelsmit and VanDerhei, 1997](#); [Hinz et al., 1997](#); [Barber and Odean, 2001](#)). We believe it is equally or more important to study gender differences in housing investment, given that housing represents a much larger proportion of the typical household's savings portfolio. Housing also differs from other common forms of household savings because prices are often determined through bilateral negotiation. In contrast, we would expect men and women to earn the same return on an investment in a S&P500 index fund (holding timing constant), even if one group were more financially sophisticated or derived greater personal utility from owning the asset.

Our findings that women negotiate worse discounts relative to the list price suggests that gender differences in negotiation contribute to the gap in housing returns. The fact that women choose to list homes at lower prices also suggests that gender differences in "first offers" within a negotiation framework may play an important role. These patterns are consistent with a large literature documenting gender differences in the ability, style, and willingness to negotiate. This literature has shown that women have more negative outcomes when negotiating in laboratory settings, as well as in labor market and automobile market settings (e.g., [Ayres, 1990](#); [Ayres and Siegelman, 1995](#); [Castillo et al., 2013](#); [Leibbrandt and List, 2014](#); [List, 2004](#); [Morton et al., 2003](#); [Reuben et al., 2015](#)).

Housing negotiations differ from standard labor market or automobile negotiations in that buyers and sellers are often advised by real estate agents, who may not perfectly share the interests of their clients.<sup>2</sup> We find that the gender gap remains similar in size after controlling for listing agent fixed

---

<sup>2</sup>Some labor market negotiations with documented gender pay gaps also involve agents, such as those in which talent agents represent professional actors or athletes. Our housing setting is also unique because personal interactions usually end after housing transactions are completed, so the gender gap cannot be explained by women placing greater value on

effects, implying that the gender gap is not driven by women systematically choosing worse agents. However, it remains possible that the same real estate agent gives different advice to men and women, or that men and women differ in whether they follow the (good or bad) advice of their agents. Our observational data unfortunately does not allow us to examine the details of discussions between clients and agents, so we leave further study of the role of agents to future work.

The unique format of housing negotiations resembles that of quasi-anonymous experimental ultimatum games. In housing negotiations, buyers and sellers typically submit written bids through agents rather than negotiating face to face, although buyers and sellers are usually aware of basic facts regarding each other's identities such as gender. Solnick (2001) studies a related ultimatum game between two players in which Player 1 chooses how to split \$10 between him or herself and Player 2. Player 2 sees the written offer and can choose to accept the offer or reject, in which case both players receive zero. The players are randomly matched and are aware of each other's genders, but remain otherwise anonymous and do not interact face to face. Solnick (2001) finds that gender significantly affects game payoffs. Player 1s, especially female Player 1s, on average offer more money to Player 2 if Player 2 is known to be male. Male Player 2s choose higher minimum acceptable offers, especially if Player 1 is known to be female. These experimental results are consistent with an important idea that may apply to housing negotiations: both men and women expect women to be more willing to share the surplus from negotiations, and are more willing to walk away from aggressive offers if those offers are proposed by women.

We caution that our results do not necessarily imply that women make mistakes in housing negotiations or have lower negotiation ability. Exley et al. (2016) show that women can experience even more negative outcomes by "leaning-in" and negotiating aggressively, and Ayres and Siegelman (1995) finds that female buyers receive worse counteroffers during automobile negotiations even when they follow identical scripts used by male buyers. Moreover, women may equal men in negotiation ability, but conduct the housing search differently because they care more about purchasing a particular home or derive greater utility from a fast, low-risk, or non-confrontational negotiation process. It is not the goal of this paper to disentangle negotiation ability from other preferences that could affect negotiated outcomes.

Regardless of the exact channel, our analysis shows that gender differences in housing returns are economically large and deserving of further research. A simple calculation implies that the housing-  

---

continued relationships, a factor that might impact labor market negotiations (Babcock and Laschever, 2009).

related gender gap in dollars is approximately \$1,600 per year for the median single female homeowner. This is approximately half as large as the unexplained gender pay gap, which has been the subject of numerous academic studies and policy debates (see e.g. [Blau and Kahn \(2017\)](#); [Card et al. \(2015\)](#)). Because housing wealth is the dominant form of savings for most households, our findings also offer insight into variation in wealth accumulation (e.g., [Ruel and Hauser \(2013\)](#)). We estimate that the gender gap in housing returns can explain approximately 30% of the overall gender gap in wealth accumulation at retirement.

Finally, our research question is related to contemporaneous work by [Andersen et al. \(2018\)](#) (AMNV), which examines gender differences in negotiations for real estate transactions in Denmark. Our analysis differs from and complements AMNV in several ways. First, AMNV (along with related earlier research by [Harding et al. \(2003\)](#)) is focused on demographic variation in negotiation and bargaining power,<sup>3</sup> while we are interested in the total gender gap in housing returns from the perspective of wealth accumulation. We are interested in factors contributing to this gender gap beyond negotiation; for instance, we show that women earn lower returns partly due to market timing.<sup>4</sup> Second, we differ from AMNV in our usage of data on both list prices and final transaction prices, which allows us to examine negotiated discounts, as well as the matching between the genders of buyers and sellers. Third, we find large gender differences in transaction prices using repeat sales data in the US, while AMNV find smaller and insignificant differences using repeat sales data in Denmark. These results complement each other, and suggest that the gender gap may vary by country and culture.

## II. Data and Measurements

In this section, we present a summary of the data sources for our analysis, describe the construction of key measures, including identification of gender, and summarize the overall data set.

### A. CoreLogic Deeds and Listings Data

Our main housing transaction data comes from data gathered by CoreLogic from county deeds records. We restrict our analysis to arms-length transactions (sales between two unaffiliated parties), and exclude non-arms-length transactions and mortgage refinancings (non-transaction deed events).

---

<sup>3</sup>[Harding et al. \(2003\)](#) uses data from the American Housing Survey and structural modeling methods to estimate how bargaining power varies with demographics.

<sup>4</sup>Our evidence of inequality in housing markets is related to earlier findings by [Bayer et al. \(2013\)](#), who use detailed panel data in four cities to show that Black and Hispanic buyers pay a 3% premium when purchasing homes. We unfortunately cannot examine racial gaps in our main data sample because we do not observe detailed demographic information for buyers and sellers, and instead infer gender from names.

Each observation reflects a housing transaction, containing information on the date of the transaction, the sale price (if the property changed hands), the exact address of the property, and the names of both sides of the transaction. This last set of data fields allows us to partially identify the gender of the participant, as well as the number of participants on each side of the transaction (discussed further below).

To supplement the transactions data with time-varying measures of the properties' characteristics, we link the deeds dataset by property location to a dataset of property listings also constructed by CoreLogic.<sup>5</sup> These data come from Multiple Listing Service (MLS) systems operated by regional real estate boards. Each listing includes a large number of fields describing the property and the status of the listing. These include when the property is listed, the list price, listing agent identification number, and the listed property features such as the number of bedrooms and bathrooms and age of the structure. If the listing sells, we observe the close date and sale price.

## B. Measurement of Gender and Relationships

We identify the gender and family structure of the buyers and seller on each transaction using reported names on the deed. For each deed record, CoreLogic reports the full name of the first and second owner on a deed, and in the case of sale, the full name of the first and second seller. We identify two pieces of information from these name fields: first, we parse the fields to identify exactly how many parties exist on each side of the transaction, since in some cases, couples are transcribed as "John and Mary Smith" in one field, rather than being split across fields as "John Smith" and "Mary Smith." Second, we use the first names to probabilistically assign a gender to each party in the transaction. We follow [Chari and Goldsmith-Pinkham \(2017\)](#) and use data from [Tang et al. \(2011\)](#) to measure the probability that a given name is male or female (based on self-reported data to Facebook). Then, for all names with probability greater than 95%, we assign either male or female gender. For those who do not match, or whose probabilities are less than 95%, we treat as unknown genders.

Identification of the number of parties, and their respective genders, allows us to group parties into four groups (on each side of the transaction): single male, single female, couples (2 individuals with both genders identified), and other, where other is the residual category and will include single individuals without gender identified, couples where only one gender is identified, couples where neither gender is identified, and institutions. For each transaction, this grouping is done both on the buyer and seller side.

---

<sup>5</sup>Properties are uniquely identified via parcel number (assigned by county deeds offices) and county code.

In a small set of counties during the earlier years of our sample period, we observe an unusually high percentage of single buyers and sellers, particularly single male buyers and sellers, and an unusually low percentage of couple buyers and sellers. Since housing records are maintained at the county level, we believe these county-years represent cases in which only one name, usually the male name, was recorded for transactions actually conducted by couples. To address this measurement issue, we impose that, in a given county-year, we are able to identify the gender and family structure (single or couple) for at least five percent of deeds, and that within this share of identified deeds, at least 20% are identified as couples, and at least five percent as single women. Otherwise, all observations in the county year are reclassified as the "other" category due to inability to credibly identify gender and family structure. The procedure reclassifies approximately 400 thousand observations.

In general, our measures of gender and relationships may be subject to measurement error. There are three types of concerns. First, we fail to identify gender for some individuals, and they will be relegated into the "Other" category. This is more likely with non-Anglo-Saxon names where the gender is less predictable based on name. Second, we may miscategorize some individuals incorrectly by gender. Given our cutoff for gender is above 95% certainty, we are less concerned about this, but it is possible. Finally, some single men and women identified in our data may actually correspond to couples who choose (or follow local convention) in recording only a single name in a real estate transaction. To ensure the robustness of our results to measurement error, we show that we can replicate our main findings using data from the American Housing Survey, where respondent gender and marital status are self reported and less likely to suffer from measurement error.

While a strength of our data is the large sample coverage, we face the limitation that we can only analyze differences in housing returns among the women, men, and couples who appear in our data. In particular, we measure a gender gap among men and women who *choose* to own housing. Our estimates are not meant to represent potential housing returns for the universe of men and women. Despite these limitations, we believe our estimates are informative of the sources of the gender gap among the large set of Americans who choose to be homeowners. Our data limitations are also similar to the limitations faced by the large literature examining the gender pay gap, which likewise can only be measured among the set of men and women who choose to work.

### C. Measuring Unlevered Returns and Levered Returns

In our full dataset of transactions, we are able to identify consecutive arms-length market transactions for each property. We focus on realized returns, earned in the period from purchase to sale. Using these consecutive transactions, we can identify the unlevered annualized return for property  $i$  in sale year  $s$ :  $r_{is} = \left(\frac{P_{is}}{P_{ib}}\right)^{\frac{1}{(s-b)}} - 1$ , where  $P_{ib}$  is the purchase price, i.e., the previous market transaction price on the property in year  $b$ . Because we observe exact dates for transactions, we allow years  $b$  and  $s$  to be non-integers to better measure the exact holding length of each property. To ensure that we correctly measure  $r_{is}$  for single male, single female, and couples, we focus on the subsample of returns that has four restrictions: (1) we have identified the gender and family structure in both periods  $b$  and  $s$ , (2) the gender and family structure of the buyer in period  $b$  corresponds to the gender and family structure in period  $s$ , (3) names of the buyers in period  $b$  is sufficiently close to the names of the sellers period  $s$  by string matching distance. This final sample is used for our analysis of housing returns. These filters substantially restrict our analysis sample, since we need to observe multiple transactions and correctly identify gender and family structure, but ensures that we are not incorrectly measuring returns. Our final returns sample contains 8.9 million observations.

Restriction (2) also ensures that we can focus on the housing returns of men and women who were identified as single at both purchase and sale. Observations in which a house is purchased by a couple and sold by a single person (which can occur after death or divorce), or purchased by a single person and sold by a couple (which can occur after marriage), are not used when comparing returns across single men, women, and couples.

In reality, the majority of homeowners in the United States buy their homes using debt, with leverage of five-to-one or higher. Moreover, this leverage tends to persist over a long period of time, with long duration mortgages whose fixed amortization schedules pay mainly interest upfront. Therefore, the real return earned is typically a levered return. Ideally, given the mortgage type, term, interest rate and downpayment, we could identify the exact levered return earned by each homeowner. However, many of these fields are missing from the data. Therefore, we compute hypothetical levered returns if the homeowner used the most common type of mortgage in the data: a 30-year fixed rate loan with an initial loan-to-value (LTV) ratio of 80% with the market interest rate in the year-quarter of the initial purchase. We also present summary statistics for the average level of leverage used by single men, women, and couples over time, as well as the rates of missing data within each group.

We measure the initial LTV as the ratio of the initial mortgage amount divided by the purchase

price. In many cases the mortgage amount is missing. In recent years, we believe missing mortgage amount represents homes purchased with cash – in 2017, for example, 28.8% of all housing transactions were done with all cash, and in the 2000s this number was around 20%.<sup>6</sup> However, in the 1990s, the share of missing mortgage amounts in our data is substantially higher, and suggests that there may also be missing data issues.

To address these data issues, we provide a simple benchmark in which we convert unlevered housing returns into levered returns assuming all purchases were done with an 80% LTV mortgage. This holds fixed any potential leverage differences across transactions, and instead converts the unlevered returns into a measure that captures the modal degree of leverage that homeowners face. Based on the purchase value and assuming 80% LTV, we calculate the initial downpayment  $D_{ib}$  and initial mortgage amount  $\text{Mortgage}_{ib}$  used to buy the home. We then calculate the average interest rate in the year-quarter of initial purchase by taking the 30-year fixed rate mortgage rate from Freddie Mac. Using this interest rate  $\rho_{ib}$ , we calculate the relative principal pay down at every monthly duration horizon, and use this to identify the share of remaining mortgage principal outstanding when the house is sold in period  $s$  ( $\text{Mortgage}_{is}$ ). This allows us to calculate the total cash out payment for the home at the time of sale:  $\text{Equity}_{is} = \max\{P_{is} - \text{Mortgage}_{is}, 0\}$ .<sup>7</sup> We then approximate the time  $b$  net present value of equity as the sum of the downpayment plus the discounted value of principal pay-down payments:  $\text{Equity}_{ib} \approx D_{ib} + \sum_{\tau=b}^s W_{i\tau} / (1 + \rho_{ib})^{\tau-b}$ . As a result, our levered annualized return is  $r_{is}^{\text{lev}} = \left( \frac{\text{Equity}_{is}}{\text{Equity}_{ib}} \right)^{\frac{1}{(s-b)}} - 1$ . Note that in the case of a full cash purchase,  $r_{it}^{\text{lev}} = r_{it}$ .

It is important to note that these calculations estimate realized levered and unlevered returns conditional on sale. Since the choice to sell a property is an economic decision based on current market conditions, these returns do not represent returns in a counterfactual world in which all homeowners are forced to sell at a fixed horizon. Instead, these measure realized returns for those homeowners who choose to sell.

#### D. Description of Data

In Table 1, we report the averages for a selection of our outcomes, broken across groups (single male, single female, couple and other) by seller type and pooled into overall averages. We are able to credibly identify the seller gender and family structure according to the criteria describe in Section B for

<sup>6</sup>See the discussion in the Wall Street Journal here, for example: <https://www.wsj.com/articles/want-that-house-you-d-better-pay-in-cash-1512469800>

<sup>7</sup>By using the max operator, we are implicitly assuming that homeowners cannot lose more than 100% of their original equity. Removing the max operator yields similar results.

approximately 40% of the sample, or around 21 million sales. Of this sample, couples have the largest share of transactions, followed by single men and then single women. We refrain from interpreting gender differences in raw sale prices in the summary statistics table, because men and women may purchase properties with different average quality. Our subsequent analysis will focus on housing returns or exploit repeat sales, which hold the property constant.

In Panel B, we report the averages for our sample of sales that are linked to listings data. This sample is substantially smaller and covers roughly 20 million sales. Approximately 50% of this sample's gender group is identified. Unsurprisingly, this sample has higher prices, since the listings data coverage is later in the sample period. We measure purchase and sale discounts as  $(\text{list price} - \text{transaction price}) / \text{list price} \times 100$ , so a larger purchase discount contributes to a higher return on housing investment and a larger sale discount contributes to a lower return on housing investment. Couple sellers give the lowest sales discount, followed by single men, single women, and then the Other group. On average, all four groups have very similar average days on market.

Finally, in Panel C, we report the averages for our sample where we observe both the purchase and the sale of a property, and we are able to confirm that the seller is the same as the buyer in the previous transaction. This restricted sample is smaller at roughly 8.9 million transactions. In this sample, we exclude the other group. We find that, on average, single men have the highest annualized unlevered return, at 8.40 percent, followed by single women at 6.85 percent, and couples at 6.46 percent. Single men hold their properties for 0.4 years less time than single women, and 0.6 years less than couples. Single men also receive greater discounts when *purchasing* the home as well, followed by couples, and then single women.

### III. Empirical Results

This section describes our regression methodology and summarizes our main results measuring the difference in returns between single men, single women, and couples. We then assess the various channels that can explain this difference in returns.

#### A. Estimation Approach

Our main analysis takes two forms. Both approaches use a simple linear regression framework to account for potential differences across gender. The first is an analysis of the unlevered and levered annualized returns:

$$r_{is} = \text{Single Female}_{is}\beta_1 + \text{Couple}_{is}\beta_2 + X_{is}\tau + \epsilon_{is}, \quad (1)$$

where  $\text{Single Female}_{is}$  is an indicator for a single female seller in period  $s$  and  $\text{Couple}_{is}$  is an indicator for a couple seller in period  $s$  in our main return sample. As a result,  $\beta_1$  and  $\beta_2$  capture the relative effect when compared to  $\text{Single Male}_{is}$ , the omitted category.  $X_{is}$  captures control variables. Without any control variables, the coefficients on  $\text{Single Female}_{is}$  and  $\text{Couple}_{is}$  measure the average raw return difference for each group relative to  $\text{Single Male}_{is}$ . We also present specifications in which  $X_{is}$  represents control variables for location and time. For instance, if  $X_{is}$  includes five-digit zip code interacted with sale-year-month fixed effects, then the main coefficients measure the average difference in returns among people who sold in the same zip code and time period.

Our second set of analyses, focusing on the channels affecting housing return, is similar but uses alternative outcome measures, such as the  $\log(\text{Sale Price}_{it})$ :

$$Y_{it} = \text{Single Female}_{it}\beta_1 + \text{Couple}_{it}\beta_2 + X_{it}\tau + \epsilon_{it}. \quad (2)$$

Since these outcomes are not measured in percent differences, we additionally include a property fixed effect in  $X_{it}$  to capture unobserved quality in the property that may be correlated with gender or family structure. To better estimate this property fixed effect, we include transactions that are not included in our returns data sample.

## B. Baseline Results

We begin by showing how housing returns differ by the gender and relationship status of the homeowner. We use observations at the sale transaction level. The sample is restricted to observations for which the gender of all sellers can be identified, and for which we can match the identity of the seller at the time of sale to the identity of the buyer at the time of initial purchase. The results are shown graphically in Figure 1 with detailed regression results reported in Table 2.

In column 1 of Table 2 Panel A, we find that single women earn 1.5 percentage points lower unlevered annualized returns than single men (the omitted category). We then explore how much of this overall gender gap can be explained by market timing, i.e., gender differences in the choice of the exact year-month in which to buy and sell. As we move from column 1 to column 5, we introduce more detailed control variables for market timing, including zip-year-month fixed effects for the initial

purchase transaction and zip-year-month fixed effects for the sale transaction. We also control for the interaction between year-month of purchase and year-month of sale fixed effects, which subsume the control variable for holding length. We find that 45% the raw gender gap in returns in column 1 can be explained by more detailed control variables for market timing. In other words, women earn lower returns partly because they are more likely to buy in locations when aggregate house prices are high and sell when they are low. However, a large gender gap persists even after introducing detailed controls for market timing. Among men and women who buy and sell in the same zip code and year-months, women still earn 0.8 percentage points lower unlevered annualized returns on housing.

We also find that couples underperform single women in terms of raw returns but outperform single women and underperform single men after adjusting for market timing. Column 1 shows that the raw return gap in annualized unlevered returns between couples and single men is 1.9 percentage points. However, the relative returns for couples are very sensitive to the inclusion of controls for market timing. As we move from column 1 to column 5, which includes comprehensive controls for market timing, we find that 79% of the return gap between couples and single men can be attributed to market timing. Among households that buy and sell in the same location and time period, couples outperform single women by 0.4 percentage points and underperform single men by 0.4 percentage points. These results indicate that couples earn lower returns primarily due to poor market timing, but outperform single women holding the location and transaction period fixed. These findings are consistent with the idea that couples (and possibly single women) face more binding timing constraints in real estate transactions due to child care and the school calendar system. In later analysis, we will examine the behavior of each group separately at purchase and sale, and find that couples underperform when purchasing, but outperform even single men when selling.

Because most home buyers purchase housing using loan-to-value ratios of 80 percent or higher, and have not paid down a large fraction of the principal at the time of sale, the real return earned is typically a levered return. Appendix Figure A5 plots the average loan-to-value (LTV) at the time of initial purchase for each gender group over time. In Panel A, we report the LTV for the sample with mortgage amount data, while in Panel B we report the share of transactions with missing mortgage data information. Single men and women have higher average LTV than couples across all years conditional on non-missing mortgage data, but also have higher rates of missing mortgage data. Because missing mortgage data can represent cash purchases or true missing data, we do not draw strong conclusions about differences in leverage across groups.

In Table 2 Panel B, we assess variation in housing returns after accounting for mortgage debt. In general, adjusting for leverage leads to a much larger gender gap in housing returns because leverage amplifies raw returns, and therefore amplifies differences in raw returns between groups. For each return observation, we compute the annualized levered return assuming the homeowner used a 30-year fixed rate mortgage with an initial 80% LTV, following the procedure described in Section C. Regression coefficients measure the the expected gender gap for households with the modal LTV of 80% in the data. We find the women underperform men by 7.9 percentage points per year after adjusting for leverage. Approximately half of the gap in levered returns can be attributed to market timing. However, women continue to underperform men by 3.7 percentage points per year after controlling flexibly for the location and timing of purchases and sales. We again find that couples underperform in terms of raw levered returns, but earn levered returns in the intermediate range after controlling for market timing: among households that buy and sell in the same zip code and year-months, couples outperform women by 2.2 percentage points and underperform men by 1.5 percentage points.

In addition to examining the gender gap in mean returns, we also compare the distribution of returns across groups. Panels A and B of Figure 2 show unlevered and levered annualized returns at various percentiles of the return distribution for each gender group. These figures report raw returns (without any adjustments for market timing). This set of figures reveal that the gender gap exists in all parts of the return distribution except for the left tail where women and men fare equally poorly. However, the gender gap is larger at the 90th percentile of the returns distribution than at the median. Couples underperform at most points of the raw return distribution, but as shown in 1, couples earn returns between that of single men and women after adjustments for market timing.

In Figure 3 Panel A, we show the density of unlevered annualized returns. The figures again show that men weakly outperform women at all parts of the return distribution, with the largest differences in the right tail. In 3 Panel B, we zoom in to the return near zero, where all groups have distributions with missing mass just to the left of zero. This dip in the distribution is consistent with loss aversion and the disposition effect (see e.g., Genesove and Mayer, 2001; Shefrin and Statman, 1985), in which people are reluctant sell at less than their initial purchase price. Finally, Figures 2 and 3 show that men do not have worse left tail outcomes than women in terms of realized returns. Therefore, compensation for greater downside risk in realized returns is unlikely to explain the higher average returns for men in our sample. However, we caution that we don't observe other adverse

outcomes such as personal bankruptcy costs that may differ by gender.

### C. Heterogeneity

In Table 3, we explore how the average gender gap in housing returns within a zip code varies with zip-level demographics from the 2010 American Community Survey. We measure the gender gap in each zip code as the average difference between male and female returns. We present the average gender gap across quartiles of various zip-level demographic characteristics. This table reports simple averages within each quartile of each demographic variable, without conditioning for other demographic variables. Observations are at the zip-code level and equally weighted. We find that the magnitude of the gender gap decreases with education, and increases with age, fraction black, and fraction single female, although the relations are not always linear. We also find that the gender gap remains large even in zip codes in the top quartile of education, income, and house prices (measured relative to the state-year-month average).

Figure 4 shows the magnitude of the average difference in unlevered returns between single men and women across each state in our sample.<sup>8</sup> The gender gap is positive in almost all states within our sample with good data coverage. We believe that variation in the gender gap across states could be partly caused by differences in data quality and estimation error across states. As noted earlier in Section B, some single men and women identified in our data may actually correspond to couples who choose (or follow local convention) to record only a single name in a real estate transaction. If the degree of estimation error also varies across states, that could contribute to variation in the estimated gender gap across states.

Figure 5 and Appendix Figure A4 show how the average and median realized returns varied over time and across gender groups. Average and median returns on housing are positive in all years of our sample, but display significant business cycle variation, with the highest returns in the run-up to the housing market crash in 2006. This is consistent with recent findings in Sakong (2019) showing a relation between cyclical housing transactions and wealth inequality. The magnitude of the gender gap in returns appears to increase with average returns, although the gender gap remains large in magnitude in recent years and does not exhibit a strong secular decline over time.

Appendix Figure A3 shows how the composition of transactions by gender group varies over time. Changing composition combined with business cycle variation in average returns implies that gender differences in market timing can play a role in the overall gender gap, but the overall shift in

---

<sup>8</sup>We exclude states where the number of observations is less than 500.

composition is relatively small.

#### D. The Gender Gap in Execution Prices

So far, we have shown that the gender gap in housing returns can be partly explained by gender differences in the market timing of when the home is purchased and sold. In this section, we explore gender variation in transaction prices, list prices, transaction discounts, among buyers and sellers who transacted in the same zip code and time period. We also discuss why the impact of a gender gap in execution prices on annualized returns depends on the holding length.

The unlevered annualized return on housing depends mechanically on the ratio of the sale price to the initial purchase price, annualized to account for holding length. To assess gender variation in each transaction price, we exploit repeat sales data and control for zip-year-month fixed effects to account for time trends within a zip code. Each observation in this analysis is a transaction. To better estimate property fixed effects, we do not restrict the sample to buyers or sellers with identified genders and matched names across sales and initial purchase. All observations corresponding to non-identified parties included and coded as the "other" category. Thus, our sample size expands to cover over 50 million observations.

The results in Table 4 show that women purchase homes at approximately 1-2% higher prices than men, holding the property fixed and adjusting for local time trends in prices. Women also sell the same property for 2-3% less than men. Couples do worse than single women in terms of purchasing at higher prices, but also outperform even single men in terms of selling at higher prices.

We can also examine how transaction prices vary with the match between categories of sellers and buyers. In Figure 6, we plot the coefficients from a regression of log transaction price on the interaction of seller gender and buyer gender, controlling for property fixed effects and zipcode by sale-year-month fixed effects. The base category is male buyers and male sellers, and each estimate should be interpreted as the relative price compared to that group. Among the four possible matches between male and female sellers and buyers, the highest transaction prices occur when there is a male seller and female buyer, and the lowest transaction prices occur when there is a female seller and male buyer.

While these results suggest that there may be strategic reasons to match with female buyers and sellers, we do not find strong evidence of unusual matching patterns. In Appendix Table A7, we examine how sellers and buyers of different genders and family structure match. We find that sellers

and buyers of the same “type” (single male, single female, and couple) tend to match with themselves slightly more than would be expected under random matching, but otherwise do not find large deviations from what would be expected under random matching.

The gender variation in transaction prices can be decomposed into gender variation in list prices and negotiated discounts relative to the list price. For this analysis, we restrict the sample in Table 4 to observations that can be matched to MLS data on home listings, leading to approximately 20 million observations, 10 million of which correspond to repeat sales. Using repeat sales, and holding the property fixed and adjusting for local time trends in listed prices, we find in Table 5 that women choose to purchase the same property when it is listed for approximately 3% higher than when it is purchased by men. Even though women purchase homes at relatively higher prices, female sellers also choose to list the same property for 1-2% less than when it is listed by men. Couples again show differential behavior at purchase and sale. Couples purchase homes that are listed for 1-2% higher than when they are purchased by men. However, couples do not choose significantly lower list prices at sale relative to single men, after adjusting for zip-year-month fixed effects.

Next, we examine how negotiated discounts vary by gender in Table 6. We measure purchase and sale discounts as the percentage discount relative to the list price,  $(\text{list price} - \text{transaction price}) / \text{list price} \times 100$ , so a larger purchase discount contributes to a higher return on housing investment and a larger sale discount contributes to a lower return on housing investment. We find that female buyers purchase homes at a 0.26 percentage point lower discount relative to men. Thus, female buyers receive lower discounts on home purchases even though they also choose to purchase properties with relatively high list prices. Further, female sellers agree to 0.092 percentage points greater discounts at sale. Thus, female sellers agree to larger discounts off the list price even though they already choose lower list prices than male sellers.

The discounts negotiated by couple buyers and sellers also display interesting patterns. Couple buyers lie between single men and women in terms of purchase discounts. However, couples negotiate more advantageous discounts than even single men when selling properties. In combination with the earlier results on list prices, we find that couple sellers list the same property at approximately equal prices set by single men, but are less likely to agree to a large discount relative to the chosen list price.

In Appendix Figure A8, we plot the full purchase and sale discount distributions. There is a large mass of discounts at exactly zero, with female buyers bunching the most at zero discount. When we

condition on positive discounts, we see that for purchase discounts, female buyers have more mass on the left than male buyers (so female buyers receive lower discounts). This behavior flips for sale discounts (so female sellers agree to larger discounts).

We can also examine how transaction discounts vary with the match between categories of sellers and buyers. In Figure 7, we plot the results from a regression of discounts on the interaction of seller gender and buyer gender, including zipcode by year-month fixed effects. The base category is male buyers and male sellers, and each estimate should be interpreted as the relative discount compared to that group. Among the four possible matches between male and female sellers and buyers, the largest discount occurs when there is a female seller and male buyer, and the smallest discount occurs when there is a male seller and female buyer.

In Tables 4-6, we used the full data sample of transaction prices and list prices, to better estimate property fixed effects from repeat sales data. The estimated coefficient for the single female indicator represents the gender gap in the dependent variable within a large data sample including home buyers and sellers that are not included in our housing returns sample (inclusion in the returns sample requires that the seller identity match the previous transaction's buyer identity). To isolate the gender gap in transaction prices, list prices, and discounts that correspond to observations in our returns sample, we present supplementary analysis in Appendix Tables A1-A3, in which the indicator variables for male, female, and couples are set equal to one only for observations in our returns sample. In order to preserve our ability to estimate property fixed effects, we categorize all other observations into the "other" category. Hence the male, female and couple dummies should only capture the effects for the subset of transactions we identify in our main returns sample, while the sample size remains the same. A caveat to this analysis is that we do not observe list prices and discounts for all observations in our returns sample, so these tables are not meant to present an exact decomposition of the estimated gender gap in housing returns. Results remain qualitatively similar.

Given the gender differences in list prices and discounts, one may wonder whether female sellers benefit from less aggressive pricing with faster transaction times. For approximately 2 million observations, we observe the number of days on market between initial listing and sale resolution. Because some houses are listed multiple times if they fail to sell, we use the earliest available listing date and list price for each transaction. In Table 7, we find that women purchase and sell homes with 2.7% shorter transaction periods relative to men (the difference falls to 1% if we control for zip-year-month fixed effects). This difference, while statistically significant, is economically small: the average trans-

action period in our data is 42 days, and single women transact one day faster. In column 3, we find that the gender gap in sale prices remains large after controlling for the days on market. In Appendix Figure A9, we plot the full distribution of days on market for each gender group, and do not see substantial differences in the right tail of the distribution, implying that male sellers are not more likely to experience unusually long transaction times.

The gender gap in list prices and transaction discounts together imply that women experience worse execution prices on real estate transactions at the points of purchase and sale. Differences in execution prices should matter much more for the annualized returns of short term investors than for the returns of long term buy-and-hold investors. In a simple model in which women buy properties for  $\delta$  fraction more and sell  $\delta$  fraction less than men and hold for  $t$  years, we expect that women will earn  $2\delta/t \times 100$  percentage points lower annualized unlevered returns than men.<sup>9</sup> In other words, the impact of a gender gap in execution prices on the gender gap in annualized returns should asymptote toward zero with holding length.

Figure 8 Panel A shows that the gender gap in annualized returns changes sharply with holding length toward zero, consistent with the intuition that differences in execution prices should matter more for the annualized returns of shorter term investors. Homeowners with shorter tenure in their properties “trade” assets more often, so any advantage or disadvantage in execution prices will matter more for their returns.<sup>10</sup>

In Figure 8 Panels B and C, we examine how the gender gap in execution prices vary with holding length. While there is some variation, the gender gap in execution prices does not asymptote toward zero as holding length increases. Women have significantly worse execution prices at purchase and sale for all holding length buckets in our sample. However, worse execution prices at the points of purchase and sale matter less for annualized returns on investment as holding period increases.

In our baseline analysis, we equally weighted each completed housing transaction (each transaction represents the annualized return from initial purchase to eventual sale by the same owner). We estimated the gender gap in housing returns, averaged across all transactions. We can instead weight

---

<sup>9</sup>Let  $P_0$  represent the market price of the property at the time of purchase. Suppose that the market value of the property grows by a fraction  $r$  each year. Suppose men buy and sell at the market price, so their annualized return equals  $r$  regardless of the holding period. Suppose that women buy properties for a fraction  $\delta$  more and sell for  $\delta$  less than the market price and hold for a period of  $t$  years. We can solve for the annualized return for women  $r_F$  such that  $[(1 + r_F)^t = (1 - \delta) * P_0 * (1 + r)^t] / [(1 + \delta) * P_0]$ . Solving for  $r_F$  after applying the approximation that  $\log(1 + x) \approx x$  for  $x$  close to zero implies that  $r_F = r - 2\delta/t$ .

<sup>10</sup>The *level* of annualized returns also declines with holding length for all groups, as shown in Appendix Figure A6. This pattern may occur due to selection, in which homeowners sell early only if they expect a high sale price that can cover transaction costs. However, the level of returns asymptotes toward 5% per year rather than zero, and cannot directly explain why the *gender gap* in returns asymptotes toward zero.

each transaction by holding length, so that each year in which a property is held receives equal weight. This alternative weighting scheme would place, e.g., six times the weight on a observation for a home held for six years relative to an observation for a home held for one year. We present results using this alternative weighting scheme for unlevered and levered returns in Panel A and B of Appendix Table A4, respectively. We find that the gender gap shrinks significantly: single women earn 0.4 percent lower unlevered returns and 1.5 percent lower levered returns relative to single men. The smaller estimated gender gap is consistent with the fact that gender differences in execution prices should matter less for annualized returns for investments with longer holding periods, and this alternative specification increases the weights on observations with longer holding periods.

#### E. Other Potential Mechanisms

In this section, we explore several other potential mechanisms which may help explain the gender gap in housing returns. First, men may select properties with characteristics associated with higher returns. In particular, men may buy riskier homes, such that their higher return represents compensation for the additional risk. Second, men may invest more in housing maintenance and upgrades, such that their real investment return is lower than implied by analysis using only the sale price and purchase price. Third, women may be older, have more children, or have lower education and income, and these demographic factors may drive the gender gap in housing returns. Fourth, men may earn higher returns because they choose better or more effective real estate agents.

In Appendix Table A5, we find that gender is predictive of the types of properties held, e.g., age of house, square footage, whether it was new construction at the time of purchase, etc. Table 8 shows that, while some of these characteristics are predictive of housing returns, controlling for detailed home characteristics does not have a large impact on the estimated magnitude of the gender gap in returns (as evidenced by the small difference in coefficients on single female between columns 2 and 3). This analysis shows that women do not, on average, sort toward a set of housing characteristics that are associated with lower returns.

Next, we explore whether men earn higher returns because they invest more in housing maintenance and upgrades. In particular, men may be more likely to purchase fixer uppers, which would explain why men buy at low prices and sell at high prices, holding the property fixed. Given that maintenance and upgrades are costly (Harding et al., 2007), men's real investment return may be lower than implied by analysis using only the sale price and purchase price. In Appendix Table A6,

we find that men are more likely to list homes that have been upgraded or renovated, but the difference in upgrade rates across genders is small. In Table 8, we find that the gender gap remains large after controlling for whether the house has been upgraded or renovated, and in Appendix Table A6, we find that the gender gap in housing returns remains large in a restricted sample for which the house listing does not mention any synonyms for upgrades, renovations, new features, expansions, etc.

Aside from upgrades and renovations that are noted in property listings, men may also invest more in routine maintenance. In Table 9 column 1, we use data on self-reported annual home maintenance costs from the American Housing Survey and find insignificant and close to zero gender differences in maintenance investment.

So far, we have shown that the gender gap remains large for homes that have not experienced major upgrades/renovations, and men and women invest similar dollar amounts into home maintenance. However, it remains possible that men invest more personal time and effort into home maintenance. To further assess the importance of gender differences in home maintenance, we return to the empirical relation between holding length and the gender gap in returns. Examining this relation will also help to rule out a risk-based story in which men purchase riskier properties.

If men invest more in maintenance each year or purchase riskier properties, then the gender gap in annualized housing returns should not decay toward zero as holding period increases. For example, if men purchase riskier properties that warrant an extra 1% return each year as compensation for risk, then the gender gap in annualized returns should asymptote toward 1% as holding period increases. We instead observe in Figure 8 a gender gap in housing returns that decays toward zero with holding period. This pattern is more consistent with a gap in returns that arises from gender differences in execution prices at the points of purchase and sale (as discussed previously, differences in execution prices of  $\delta$  predicts that the gender gap equals  $2\delta/t$  which approximately matches the shape of the decay in the data).

We can also use detailed demographic data from the American Housing Survey to explore whether demographic factors correlated with gender may help explain the gender gap in housing returns. Women outlive men on average, and older individuals may earn worse returns on housing.<sup>11</sup> Women may also have more children, lower education, and lower income, factors that may impact housing

---

<sup>11</sup>After the death of a spouse, widows or widowers may sell homes at a discount for a variety of reasons. Such cases are excluded from our returns analysis because we require that the homeowner be single at the time of home purchase as well as the time of home sale in order to be classified as single male or single female. We also restrict our sample to arms-length transactions, which excludes transfers to family members.

returns.

Table 9 presents regression analysis using American Housing Survey data. In column 3, we are able to replicate our baseline results of a gender gap in housing returns using this alternate data source. This shows that our baseline results are unlikely to be due to measurement error in the identification of gender and household status, since these fields are self-reported rather than imputed in the American Household Survey. Interestingly, the gender gap in realized returns in column 3 exceeds the gender gap in self-reported estimated returns in column 2, which uses self-reported estimates of current property values to calculate returns. This comparison suggests that women may underestimate their investment return disadvantage in housing markets. In column 4, we show that number of children, ethnicity, and income all significantly predict realized housing returns. A greater number of other adults in the home (which may represent care given to elderly relatives) and lower education also predict lower returns, although the coefficients are not statistically significant. However, the gender gap remains large at 1 percentage point per year after controlling for all of these demographic variables.

In column 5, we explore how having children may impact single men, women, and couples differently. The omitted category in this regression is single male without any children. For all groups, we find that having children is associated with lower returns on housing (having at least one child lowers the annualized return for single men and women by approximately 1 percentage point, and the returns of couples by 0.5 percentage points). However, single women without any children still earn 1 percentage points lower returns relative to single men without children, after controlling for education, income, and ethnicity.

The gender gap in housing returns could also arise because men employ better or more effective real estate agents. Housing transactions are typically intermediated by agents who advise their clients on the choice of listing prices, offers, and counter offers in real estate negotiations. Using merged MLS data, we observe unique codes for each listing agent representing the seller. In Table 10, we re-estimate the gender gap in returns, discounts, list prices, and transaction prices, after controlling for listing agent fixed effects. The agent fixed effects control for the fixed impact of each agent on prices, discounts, etc. across all transactions in our data. In other words, we can control for the fixed impact of agent gender, talent, effort, experience, etc. on housing transactions. We continue to find similarly sized gender gaps in returns, discounts, list prices, and transaction prices after controlling for agent fixed effects. Thus, the gender gap cannot be explained by the possibility that single women

match with worse seller agents. An important caveat to this analysis is that we can only rule out the influence of agent effects that are *fixed* across clients. The impact of agents may depend on the interaction between agents and the gender of their clients. For example, the same real estate agent may give different advice to male and female clients. Men and women may also differ in whether they follow the (good or bad) advice of their agents. Our observational data unfortunately does not allow us to examine the details of discussions between clients and agents, so we leave further study of the role of agents to future work.

Finally, we explore how the gender gap in housing markets varies with market tightness in Table 11. To measure market tightness, we use our listings data to construct a county-by-month measure of the number of sales in a given month scaled by the total number of listings. As markets tighten, demand for the average listing increases and the housing market becomes more liquid. We then replicate our analyses from Table 2, 4 and 6, interacting our measures of gender with market tightness. We find that the gender gap in returns, prices, and discounts shrinks substantially with market tightness. As market tightness increases, the gender gap in returns would approximately approach zero when market tightness is around 1. We find similar offsetting interaction coefficients for transaction prices and discounts.

This pattern suggests that bilateral negotiation may be an important driver of the average gender gap in housing returns. As markets tighten, bilateral negotiation is often replaced with quasi-auctions, in which multiple interested buyers simultaneously bid for homes. The reduction in the gender gap with market tightness is also inconsistent with an explanation in which men buy riskier properties or invest more in home maintenance and upgrades. Differences in maintenance or risk should lead to real differences in home value appreciation that would, if anything, be more efficiently priced in liquid markets. Similarly, variation by market tightness is inconsistent with the idea that women earn lower housing returns because they derive greater utility from housing and are therefore willing to pay more for the same house. If so, women should also submit higher bids for homes, leading to lower returns in tight housing markets.

#### IV. Discussion and Implications

Overall, we believe the gender gap in housing returns arises because of differences in market timing and differences in negotiated execution prices among homes sold in the location and time period. What happens in between purchase and sale, e.g., potential mechanisms in which men invest more in

upgrades and maintenance or buying riskier properties that naturally earn higher returns, appear to be less important explanations. We also believe that the root causes of gender differences in market timing and negotiated outcomes may be complex and are deserving of further research. For example, women may engage in less advantageous market timing not because they don't understand market conditions, but because they face timing constraints. Women may have worse negotiated outcomes for a variety of reasons, including expectations regarding how women should behave (e.g., [Egan et al. \(2017\)](#)), preferences and beliefs regarding negotiation strategy which may be context dependent (e.g., [Bordalo et al. \(2019\)](#)), willingness or ability to search, etc.

Regardless of the exact channel, our analysis shows that gender differences in housing returns are economically large. In our main analysis, we presented percentage point gender gaps in housing returns, transaction prices, and negotiated discounts. We can also think about the gender gap in terms of dollars lost per year for the median single female homeowner. We assume that a woman holds a home worth \$200,000 (the median home value from the 2013-2017 American Community Survey five-year estimates) for the median holding period of five years, and experiences a 2% execution price disadvantage at the points of purchase and sale. These assumptions imply that women lose \$1,600 each year as a homeowner relative to single men. We can compare this magnitude to the dollar loss from the gender pay gap. [Blau and Kahn \(2017\)](#) estimate a gender pay gap of 8% among similar men and women in terms of education, occupation, and other observables. Based on the median wage for single men of \$35,000 per year, the gender pay gap implies that women with similar observables earn \$2,800 less per year. Thus, the gender gap in housing markets is approximately half as large as the gender pay gap, which has been the subject of numerous academic studies and policy debates.

Because housing wealth is the dominant form of savings for most households, our findings also offer insight into variation in wealth accumulation (e.g., [Ruel and Hauser \(2013\)](#)). Appendix Figures [A1](#) and [A2](#) report equity in housing as a percentage of total net worth and the gender gap in wealth accumulation at retirement, respectively. We estimate the impact of gender differences in the housing market on wealth accumulation under various assumptions. The details of this calculation are reported in the Appendix. We estimate that the gender gap in housing returns can explain approximately 30% of the overall gender gap in wealth accumulation at retirement.

Moreover, these calculations may represent conservative estimates of the gender gap in dollars. The calculations use average differences in execution prices, which are measured among men and women who transact in the same zip code and year-month. The calculations do not take into account

the significant gender differences in market timing. The gender gap in dollars would be larger if we allow women to be more likely to buy when aggregate prices are high and sell when they are low.

Finally, we emphasize that women may derive greater utility from home ownership despite earning lower financial returns. Therefore, we do not draw conclusions regarding gender gaps in welfare. However, we also believe that a simple explanation in which women value housing more than men is unable to fully match the empirical patterns documented in this paper. In particular, it does not explain why women buy homes for more, but also sell for less. It does not explain why women negotiate worse discounts when facing male counterparties. It also does not explain why the gender gap approaches zero in tight housing markets. If women attach higher valuations to homes, they should submit higher bids when multiple potential buyers submit competing bids, leading to lower returns for women in tight housing markets.

## V. Conclusion

We uncover a large gender gap in the returns to housing investment in recent decades in the US. This gender gap is likely to be an important contributor to gender differences in wealth accumulation, given that housing wealth represents the dominant form of savings for most US households. Using detailed data on housing transactions across the US, we find that single men earn 1.5 percentage points higher unlevered returns per year on housing investment relative to single women, with couples occupying the intermediate range. However, the real return on housing earned by most households is a levered return. The gender gap in raw returns grows significantly larger after adjusting for mortgage borrowing. Assuming the modal 80% LTV, men earn approximately 7.9 percentage points higher levered returns per year relative to women. Using data on repeat sales, we show that women buy the same property for approximately 2% more and sell for 2% less. The gender gap in housing returns arises because of gender differences in the location and timing of transactions, choice of initial list price, and negotiated discount relative to the list price. While the gender gap varies with demographic characteristics, it remains substantial in regions with high average education, income, and house price levels. It also has not displayed a secular decline over time.

In addition to gender gaps resulting from market timing, we find that women experience significantly more negative negotiation-related outcomes in housing markets. Women negotiate smaller discounts relative to the list price when buying and offer larger discounts when selling. Holding the property fixed, the highest transaction prices occur in cases with a male seller and female buyer,

and the lowest transaction prices occur in cases with a female seller and male buyer. However, these results do not necessarily imply that women make mistakes in housing negotiations. In particular, recent research by [Exley et al. \(2016\)](#) suggests that women can sometimes experience even more negative outcomes by "leaning-in" and negotiating more. Given the importance of housing investment for household savings, we believe that further exploration of factors that determine the gender gap in housing is an important direction for future research.

**Figure 1:** Annualized returns by gender group across different specifications

**Note:** This figure plots the coefficients for Single Female and Couples from Table 2. Panel A and B correspond to the corresponding estimates in Panel A and B of Table 2. The levered returns are calculated following the formula in Section C, assuming an initial LTV of 80%. See Section II.B for more details on the definition of gender and family structure.

**Figure 2:** Distribution of annualized returns by gender group

**Note:** This figure plots summary statistics for the annualized returns for housing transactions by three gender groups: couples, single women, and single men. The levered returns are calculated following the formula in Section C, assuming an initial LTV of 80%. The first column in each set is for couples, the second is for single women, and the third is for single men. See Section II.B for more details on the definition of gender and family structure.

**Figure 3:** Density of unlevered annualized returns by gender group

**Note:** This figure plots the density of the annualized unlevered returns for housing transactions by three gender groups: couples, single women, and single men. Returns are truncated at -50% and +100% in Panel A. Returns are truncated at -4% and +5% Panel B. See Section II.B for more details on the definition of gender and family structure.

Figure 4: Gender gap in unlevered returns across states

**Note:** This figure plots the average difference in unlevered annualized returns between single men and women across states. The points represent the estimated difference in realized returns, while the bars represent the 95% confidence interval. Standard errors are clustered at the zip-code level. See Section II.B for more details on the definition of gender and family structure.

**Figure 5: Average unlevered returns over time by gender group**

**Note:** This figure plots the average unlevered annualized return for couples, single women, and single men by sale year. As our sample begins in 1991, we begin this figure in 1995 to allow for sufficient data to avoid truncation. See Section II.B for more details on the definition of gender and family structure.

**Figure 6:** Transaction price by seller-buyer gender pairing

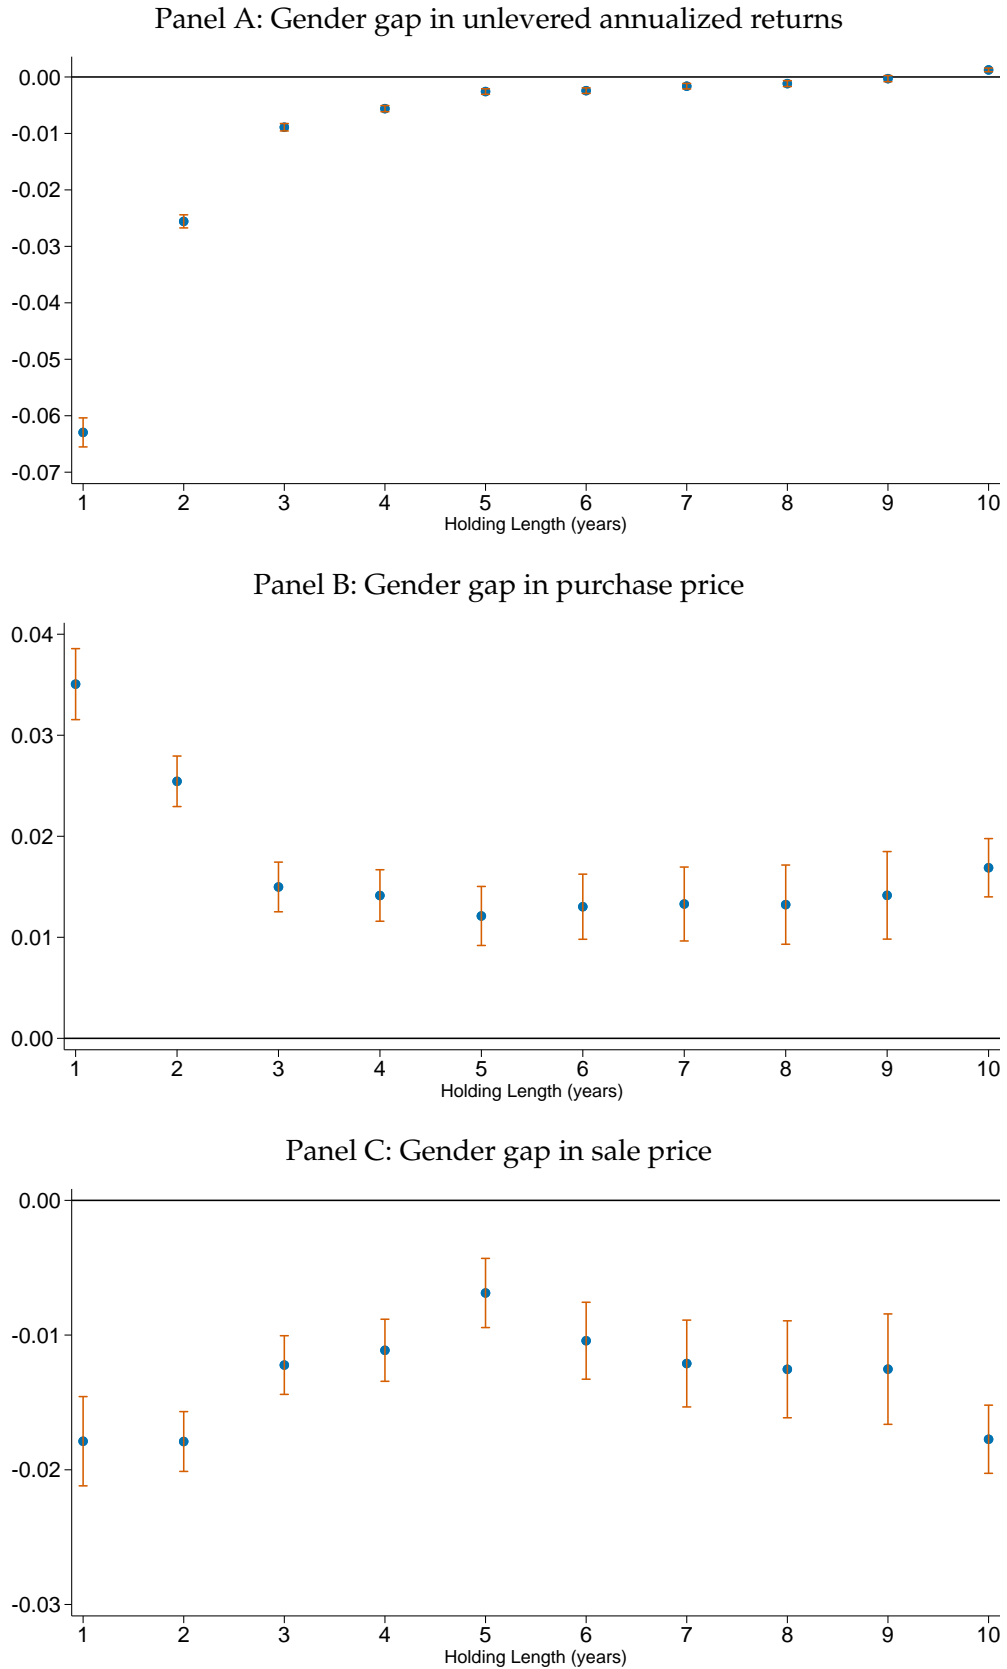

**Note:** This figure plots the average difference in transaction prices for each possible seller-buyer gender pair, relative to transactions involving single male sellers and single male buyers. These estimates come from a regression of the form in Table 4 column 4, but allowing for the buyer and seller gender to interact. We plot only the coefficients representing single male or female buyers and sellers, with male seller-male buyer as the omitted base coefficient. See Section II.B for more details on the definition of gender and family structure.

**Figure 7: Discounts by seller-buyer gender pairing**

**Note:** This figure plots the average difference in discounts for each possible seller-buyer gender pair, relative to discounts for transactions involving single male sellers and single male buyers. We measure discounts as  $(\text{list price} - \text{transaction price}) / \text{list price} \times 100$ , so a larger discount contributes to a higher return on housing investment for buyers and a lower return for sellers. These estimates come from a regression of the form in Table 6 column 4, but allowing for the buyer and seller gender to interact. We plot only the coefficients representing single male or female buyers and sellers, with male seller-male buyer as the omitted base category. See Section II.B for more details on the definition of gender and family structure.

**Figure 8:** Differences between single men and women by holding period

**Note:** This figure plots the average difference in outcomes between single men and women by holding length for the property. We exclude holding periods longer than 11 years. Panel A plots the male minus female gender gap in returns controlling for zip-sale-year-month fixed effects. Panels B and C plot the female minus male gender gap in log purchase and sale prices, respectively, controlling for property fixed effects and zip-year-month fixed effects.

**Table 1: Summary statistics**

	Gender Group				Overall
	Single Male	Single Female	Couple	Other	
<b>Panel A: Full Sample</b>					
Log(Sale Price)	12.0264	11.9572	12.1414	12.0748	12.0704
Sample Size	6,092,999	5,110,755	9,960,567	31,719,545	52,883,866
<b>Panel B: Listing Sample</b>					
Log(Sale Price)	12.1445	12.0673	12.2723	12.0342	12.1096
Log(List Price)	12.1267	12.0593	12.2702	11.9397	12.0547
Sale Discount (p.p.)	2.8219	2.9891	2.5418	3.1084	2.9261
Log(Days on Market)	3.7193	3.6984	3.7033	3.7845	3.7467
Sample Size	2,542,710	2,475,414	4,640,709	10,384,231	20,043,064
<b>Panel C: Returns Sample</b>					
Log(Sale Price)	12.1699	12.0844	12.3354	-	12.2292
Annualized Unlevered Returns	0.0840	0.0685	0.0646	-	0.0712
Annualized Levered (80%) Returns	0.3024	0.2237	0.2062	-	0.2389
Holding Length (Years)	5.3427	5.7665	5.9889	-	5.7456
Log(Purchase Price)	11.9294	11.8477	12.0807	-	11.9828
Purchase Discount (p.p.)	2.7852	2.5149	2.5711	-	2.6240
Sample Size	2,666,894	2,021,915	4,244,322	-	8,933,131

**Note:** This table reports the summary statistics for the samples used in the analysis, split by four seller gender groups (single male, single female, couple and other), and also pooled. Each cell is the overall mean within the relevant the sample group. Panel A represents the full sample of all arms-length sales transactions reported in the data. Panel B represents the sample of sales transactions successfully matched to listings data. Panel C represents the sample of sales transactions where we successfully match the identified gender and family structure in the sale transaction with that in the previous purchase transaction, and also match the names of the sellers with the names of the buyers in the previous transaction. See Section II.B for more details on how we identify gender and family structure. See Section II.A for more details on how we match the data.

**Table 2: Unlevered returns: market timing**

Panel A: Unlevered Returns					
	Unlevered Ann Return				
	(1)	(2)	(3)	(4)	(5)

Zip-BuyYM FE	No	No	No	Yes	Yes
SaleYM FE x BuyYM FE	No	No	No	No	Yes
R-squared	0.004	0.292	0.326	0.481	0.628
Observations	8,933,131	8,933,131	8,933,131	8,933,131	8,933,131

**Note:** This table shows how housing returns differ by the gender and relationship status of the homeowner, after introducing control variables for the timing of housing transactions. Standard errors are clustered by zipcode. \*, \*\*, and \*\*\* denote statistical significance at the 10%, 5%, and 1% level, respectively.

**Table 3:** Heterogeneity by zip-level demographics: quartile averages

Male - Female Unlevered Ann Return	Quartile 1	Quartile 2	Quartile 3	Quartile 4
	(1)	(2)	(3)	(4)
Frac Black	0.0137	0.0140	0.0143	0.0194
Frac HS Education or Less	0.0089	0.0146	0.0196	0.0240
Frac 60+	0.0118	0.0154	0.0182	0.0184
Frac Single Female	0.0115	0.0135	0.0150	0.0222
Median Family Income	0.0234	0.0177	0.0145	0.0109
House Price	0.0191	0.0165	0.0139	0.0118

**Note:** This table presents the average gender gap in unlevered annualized housing returns across quartiles of various zip-level demographic characteristics from the 2010 American Community Survey. This table reports simple averages within each quartile of each demographic variable, without conditioning for other demographic variables. Observations are at the zip-code level and equally weighted.

**Table 4:** Transaction price

	Log(Purchase Price)		Log(Sale Price)	
	(1)	(2)	(3)	(4)
Single Female	0.013*** (0.001)	0.018*** (0.001)	-0.029*** (0.001)	-0.026*** (0.001)
Couple	0.029*** (0.002)	0.032*** (0.001)	0.014*** (0.001)	0.016*** (0.001)
Other	0.091*** (0.005)	0.022*** (0.003)	-0.051*** (0.002)	-0.051*** (0.001)
Property FE	Yes	Yes	Yes	Yes
Year-Month FE	Yes	No	Yes	No
Zip-Year-Month FE	No	Yes	No	Yes
R-squared	0.794	0.886	0.793	0.886
Observations	52,883,866	52,883,866	52,883,866	52,883,866

**Note:** This table examines gender variation in transaction prices. We use repeat sales data that allows us to control for property fixed effects. We also control for zip-year-month fixed effects to account for time trends within a zip code. Each observation is a transaction. To better estimate property fixed effects, we do not restrict the sample to buyers or sellers with identified genders and matched names across sales and initial purchase. All observations corresponding to non-identified single women, single men, and couples are included and coded as the "other" category. Single males are the omitted category. Standard errors are clustered by zipcode. \*, \*\*, and \*\*\* denote statistical significance at the 10%, 5%, and 1% level, respectively.

**Table 5: List price**

	Log(Purchase List Price)		Log(Sale List Price)	
	(1)	(2)	(3)	(4)
Single Female	0.034*** (0.001)	0.032*** (0.001)	-0.020*** (0.001)	-0.017*** (0.001)
Couple	0.023*** (0.001)	0.014*** (0.001)	-0.005*** (0.001)	0.000 (0.001)
Other	-0.057*** (0.002)	-0.061*** (0.002)	-0.122*** (0.002)	-0.096*** (0.002)
Property FE	Yes	Yes	Yes	Yes
Year-Month FE	Yes	No	Yes	No
Zip-Year-Month FE	No	Yes	No	Yes
R-squared	0.783	0.842	0.784	0.842
Observations	10,984,588	10,984,588	10,984,588	10,984,588

**Note:** This table examines gender variation in list prices chosen by home sellers. We use repeat sales data that allows us to control for property fixed effects. We also control for zip-year-month fixed effects to account for time trends within a zip code. Each observation is a listing matched to a sales transaction and the sample is restricted to properties for which we observe at least two transactions. To better estimate property fixed effects, we do not restrict the sample to buyers or sellers with identified genders and matched names across sales and initial purchase. All observations corresponding to non-identified single women, single men, and couples are included and coded as the "other" category. Single males are the omitted category. Standard errors are clustered by zipcode. \*, \*\*, and \*\*\* denote statistical significance at the 10%, 5%, and 1% level, respectively.

**Table 6:** Discount relative to the list price

	Purchase Discount		Sale Discount	
	(1)	(2)	(3)	(4)
Single Female	-0.276*** (0.007)	-0.256*** (0.005)	0.167*** (0.007)	0.092*** (0.005)
Couple	-0.117*** (0.012)	-0.084*** (0.005)	-0.280*** (0.012)	-0.228*** (0.005)
Zip-Year-Month FE	No	Yes	No	Yes
R-squared	0.001	0.222	0.002	0.257
Observations	13,690,139	13,690,139	9,658,833	9,658,833

**Note:** This table examines how negotiated transaction discounts vary by gender. We measure purchase and sale discounts as  $(\text{list price} - \text{transaction price}) / \text{list price} \times 100$ , so a larger purchase discount contributes to a higher return on housing investment and a larger sale discount contributes to a lower return on housing investment. Standard errors are clustered by zipcode. \*, \*\*, and \*\*\* denote statistical significance at the 10%, 5%, and 1% level, respectively.

**Table 7: Days on market**

	Sale Log(Days on Mkt)		Log(Sale Price)
	(1)	(2)	(3)
Single Female	-0.027*** (0.002)	-0.009*** (0.002)	-0.024*** (0.001)
Couple	-0.048*** (0.002)	-0.049*** (0.002)	-0.006*** (0.001)
Other	-0.002 (0.003)	-0.049*** (0.003)	-0.087*** (0.002)
Sale Log(Days on Mkt)			0.002*** (0.000)
Property FE	No	Yes	Yes
Zip-Year-Month FE	Yes	Yes	Yes
R-squared	0.283	0.659	0.937
Observations	10,412,065	10,412,065	10,412,065

**Note:** This table examines how days on market, measured as the number of days between listing and sale, varies with gender, and contributes the gender gap in housing returns. Standard errors are clustered by zipcode. \*, \*\*, and \*\*\* denote statistical significance at the 10%, 5%, and 1% level, respectively.

**Table 8: Controlling for timing and property characteristics**

	Unlevered Ann Return		
	(1)	(2)	(3)

Observations	124,505	135,669	3,716	3,678	3,678

**Note:** This table uses data from the American Housing Survey. In column 1, the dependent variable is reported annual maintenance scaled by home purchase price. In column 2, estimated unlevered return is the annualized unlevered return, calculated using the homeowner's self reported estimate of current home value relative to purchase price. In column 3, real unlevered return is the annualized unlevered return, calculated using the actual purchase price and sale price. Standard errors are double clustered by household and survey year. \*, \*\*, and \*\*\* denote statistical significance at the 10%, 5%, and 1% level, respectively.

**Table 10: Controlling for listing agents**

**The Gender Gap in Housing Returns**  
Paul Goldsmith-Pinkham   Kelly Shue

## A. Impact on Wealth Accumulation

In this section, we estimate that gender differences in the housing market can explain up to 30% of the gender gap in wealth accumulation at retirement.<sup>12</sup>

Before proceeding to the calculations, we note that wealth is measured at the household level and shared by married couples. Therefore, we estimate wealth accumulation by women and men who remain single until retirement, which represent approximately 10 and 13 percent of the US population, respectively.<sup>13</sup> Our calculations are not meant to represent women and men in general, many of whom are married or experience changes in marital status over their lifetimes. Our estimations may still be informative when considering the welfare of married individuals because we offer insight into each party's financial outside options if they were to remain single, which may affect bargaining power within married households. The limitations of our calculations are similar to those faced when considering how the gender pay gap contributes to differences in wealth accumulation, which likewise can only be estimated for single households but may matter for bargaining power and welfare within married households.

We assume that men and women buy their first house at age 30. They remain homeowners until age 65 when they retire and sell their home. House value grows at 2.5% annually. People pay off their mortgages in full by retirement and remain single from age 30 to 65. People move to new homes four times, at ages 35, 40, 45, and 54 (this timing is designed so that people move less frequently as they age). Men and women invest the same initial amount in housing at age 30 and do not move additional income into housing other than to cover transaction costs, which we assume to be the same for men and women. Men trade at fair market prices whereas women lose 2% of housing wealth at each house purchase and sale.

Under these assumptions, women accumulate 18.4% lower housing wealth relative to men by age 65. Intuitively, the difference arises because the initial male investment in housing grows at a rate of 2.5% annually. The initial female investment in housing grows at the same rate, but women experience a loss of 2% of housing wealth at each purchase and sale.

The gender gap in median net worth at retirement for single homeowners is approximately 40%,<sup>14</sup> and a single woman with the median level of wealth has 70% of her net worth invested in housing (see Appendix Figures A1 and A2). This implies that approximately 32.3% ( $= 70\% \times 18.4\%/40\%$ ) of the gap in wealth accumulation at retirement can be explained by the gender gap in housing markets.

We can modify our baseline calculation by changing the number of housing transactions. Women are less disadvantaged if they engage in fewer transactions. We assume that people move three times instead of four, at the ages of 35, 42, and 52, between the initial purchase at age 30 and final sale at age 65. Under these modified assumptions, the gender gap in housing wealth at retirement is 15.0%, implying that 26.3% of the gap in total wealth accumulation can be explained by the gender gap in housing markets.

We can also modify our baseline calculation by allowing people to invest more in housing with each move. This is equivalent to allowing people to contribute to their housing portfolio over time by moving to more expensive homes. We assume that men invest an additional 15% of the market value of their current house into their next house each time they move. We assume women move at the same time and invest the same additional dollar amount as men each time they move. Under these modified assumptions, the gender gap in housing wealth at retirement is 14.3%, implying that 25.1% of the gap in total wealth accumulation can be explained by the gender gap in housing markets.

These estimates may be conservative because they rely on an estimate of the gender gap in execution prices at purchase and sale, which comes from regression results in Table 4, which control for

---

<sup>12</sup>We thank Tim Landvoigt for recommending this exercise and for detailed suggestions regarding execution.

<sup>13</sup>The numbers come from the 2018 American Community Survey, and represent the percentage of never married women and men aged 55 to 64.

<sup>14</sup>Our estimate of the gender gap in wealth accumulation is similar to the estimated gap of 36% for never-married men and women at age 65 presented in Ruel and Hauser (2013).

property fixed effects and zip-year-month fixed effects. These regressions estimate the gender gap in execution prices among men and women who choose to transact in the same zip-year-month. Our calculation does not take into account that women also earn lower returns due to market timing, in that they are more likely to buy when aggregate prices are high and sell when they are low.

**Figure A1:** Share of net worth invested in stocks versus housing, Survey of Consumer Finances

**Note:** This figure plots the average share of net worth invested into housing and stocks across the wealth distribution, for individuals between the ages of 60 and 70, split by single women, single men and couples. Single women and single men are defined by gender of head of household, and not living with a partner. Couples are defined as those living with partner or married. Housing share is total housing equity divided by net worth. Stock share is the share of wealth in all equity investments (including retirement accounts, IRA/Keogh accounts, directly held pooled investment funds held by household, directly held stocks held by household, account-type pension plans from the head of household and spouse’s current jobs, and trusts investments) scaled by overall net worth. Both variables are set to zero if the numerator is negative or zero, or net worth is negative or zero. We pool across all years in the Survey of Consumer Finance (1989-2016), and all variables are measured in 2016 dollars.

**Figure A2: Wealth at retirement, Survey of Consumer Finances**

Panel A: Median Networth of Homeowners, age 60-70

Panel B: Mean Networth of Homeowners, age 60-70

**Note:** This figure plots the mean and median net worth across couples, single males, and single females between the ages of 60 and 70. Age is defined by the head of the household, as reported in the survey. Single women and single men are defined by gender of head of household, and not living with partner. Couples are defined as those living with partner or married. We pool across all years in the Survey of Consumer Finance (1989-2016).

**Figure A3:** Composition of transactions by gender group over time

**Note:** This figure plots the relative composition of sale transactions across couples, single males, and single females within the sample of transactions used for returns estimation. See Section II.B for more details on how we identify gender and family structure.

**Figure A4:** Median unlevered returns over time by gender group

**Note:** This figure plots the median unlevered annualized return for couples, single women, and single men by sale year. As our sample begins in 1991, we begin this figure in 1995 to allow for sufficient data to avoid truncation. See Section II.B for more details on the definition of gender and family structure.

**Figure A5: Original LTV over time by gender group**

**Note:** This figure presents information on LTV at time of purchase across couples, single women, and single men. In Panel A, we plot the average LTV at time of purchase, conditional on having on mortgage data. In Panel B, we plot the share of transactions with missing mortgage data. This combines two forces: full cash transactions and observations with pure missing data.

**Figure A6:** Unlevered returns by holding period

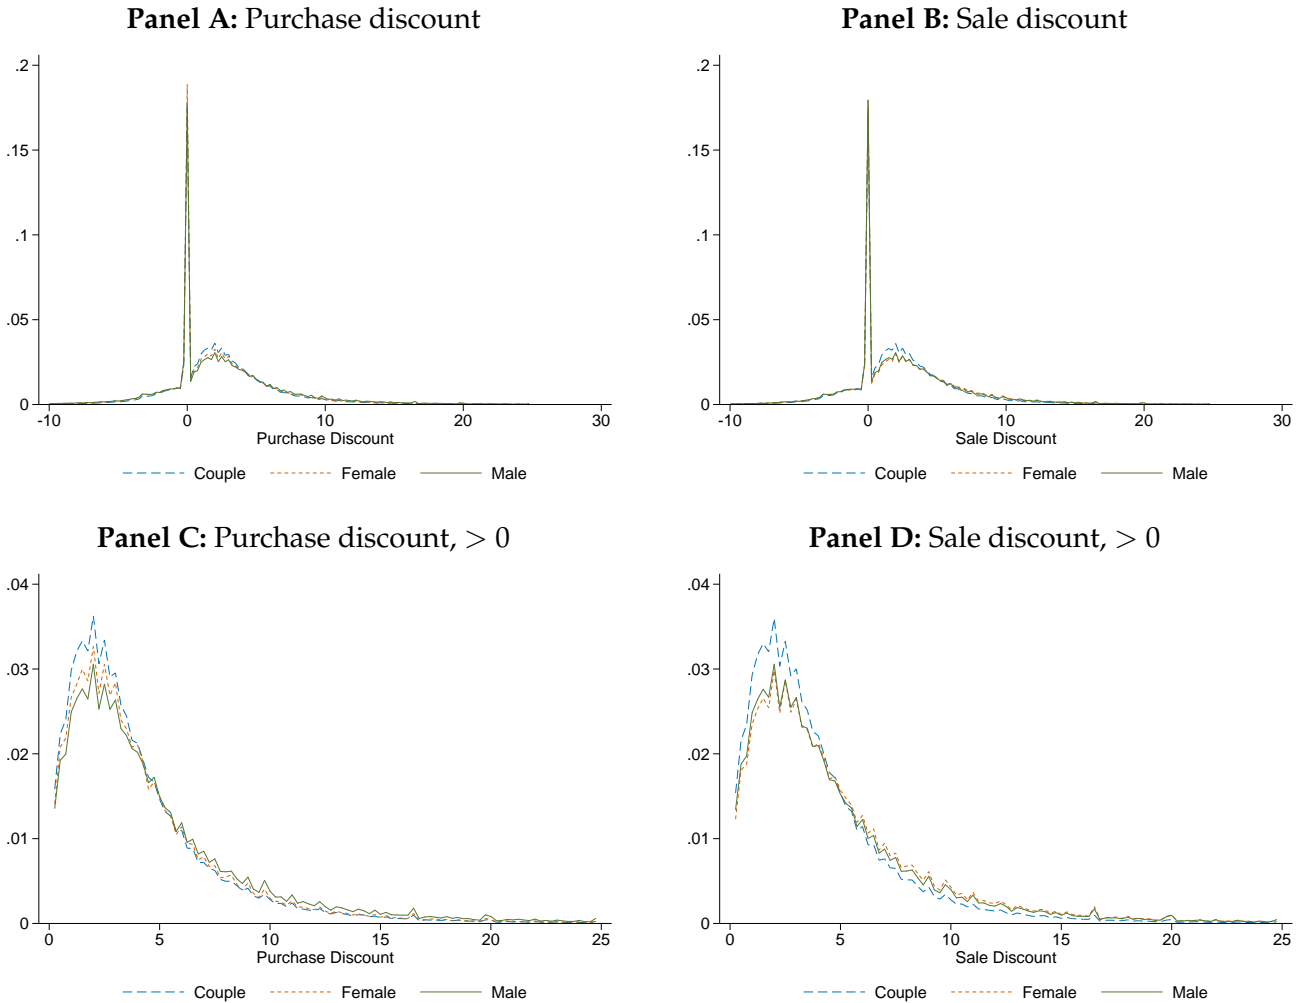

**Note:** This figure plots the average unlevered annualized returns for couples, single women, and single men by holding period. We exclude holding periods longer than 11 years. See Section II.B for more details on the definition of gender and family structure. See Appendix Figure A7 for the relative distribution of transactions across holding lengths.

**Figure A7: Transaction share by holding length**

**Note:** This figure plots the distribution of transactions for couples, single women, and single men across holding lengths without our returns sample. We restrict the sample to properties with a minimum of holding period of 3 months.

**Figure A8: Sale and purchase discount distributions**

**Note:** This figure plots the distribution of purchase and sale discounts for couples, single women and single men. We measure discounts as  $(\text{list price} - \text{transaction price}) / \text{list price} \times 100$ , so a larger purchase discount contributes to a higher return on housing investment and a larger sale discount contributes to a lower return on housing investment. In Panel A and B, we plot the full distributions for all three groups. In Panel C and D, we restrict the distribution to values greater than zero to exclude the spike at 0. See Section II.B for more details on the definition of gender and family structure.

**Figure A9: Days on market distribution**

**Note:** This figure plots the distribution of days on market for listings sold by couples, single women, and single men. See Section II.B for more details on the definition of gender and family structure.

**Table A1:** Transaction price, focus on subsample with returns data

	Log(Purchase Price)		Log(Sale Price)

Observations	8,933,131	8,933,131	8,933,131	8,933,131	8,933,131

**Note:** This table re-estimates Table 2, weighting each observation by holding length. Standard errors are clustered by zipcode. \*, \*\*, and \*\*\* denote statistical significance at the 10%, 5%, and 1% level, respectively.

**Table A5:** Selection of property characteristics

	New Construction	Log(House Age)	Log(Sq Ft)
	(1)	(2)	(3)
Single Female	0.003*** (0.000)	-0.021*** (0.003)	-0.066*** (0.001)
Couple	0.033*** (0.001)	-0.137*** (0.004)	0.143*** (0.002)
Zip-Year-Month FE	Yes	Yes	Yes
R-squared	0.271	0.513	0.445
Observations	8,933,131	2,131,508	1,937,762

**Note:** This table examines gender differences in preferences for property characteristics. Standard errors are clustered by zipcode. \*, \*\*, and \*\*\* denote statistical significance at the 10%, 5%, and 1% level, respectively.

**Table A6: Upgrades**

	Had Upgrades	Returns (Not Upgraded)	Returns (Upgraded)
	(1)	(2)	(3)
Single Female	-0.010*** (0.001)	-0.010*** (0.000)	-0.017*** (0.000)
Couple	0.000 (0.001)	-0.009*** (0.000)	-0.020*** (0.001)
Zip-Year-Month FE	Yes	Yes	Yes
R-squared	0.296	0.415	0.387
Observations	3,432,795	2,330,733	1,102,062

**Note:** Properties are considered to be upgraded if the listing text contain synonyms for upgrades, renovations, new features, or expansions. Column 1 measures relative upgrade rates across gender groups. Columns 2 and 3 estimates the gender gap in unlevered annualized returns for subsamples of the data that have not been upgraded or have been upgraded, respectively. The sample is restricted to observations that are matched to listings with non-missing property descriptions. Standard errors are clustered by zipcode. \*, \*\*, and \*\*\* denote statistical significance at the 10%, 5%, and 1% level, respectively.

**Table A7: Match rates**

Panel A: Overall Match Rates

Seller Gender	Buyer Gender			Overall
	Single Male	Single Female	Couple	
Single Male	0.1385 [0.1207]	0.0868 [0.0830]	0.1010 [0.1225]	0.3262
Single Female	0.0936 [0.0901]	0.0748 [0.0620]	0.0752 [0.0915]	0.2437
Couple	0.1378 [0.1591]	0.0930 [0.1095]	0.1993 [0.1615]	0.4301
Overall	0.3700	0.2546	0.3755	1

Panel B: Zip-Year-Quarter Match Rates

Seller Gender	Buyer Gender			Overall
	Single Male	Single Female	Couple	
Single Male	0.1503 [0.1400]	0.0997 [0.0936]	0.1141 [0.1204]	0.3372
Single Female	0.1032 [0.0990]	0.0869 [0.0736]	0.0866 [0.0940]	0.2535
Couple	0.1533 [0.1596]	0.1088 [0.1171]	0.2225 [0.2000]	0.4642
Overall	0.3799	0.2696	0.3958	1

**Note:** This table presents the joint probability of a seller of a given gender and family type matching with a buyer of a given gender and family type. The first number in each cell is the empirical match rate as seen in the data. The number in brackets is the theoretical number if match rates were random (using the product of the two marginal empirical rates). Non-categorized genders and family types are excluded from the matching exercise. Panel A pools the full sample, while Panel B calculates the actual and random match rates at the zip-year-quarter, and then takes the unweighted average across zip-year-quarters.
